## Abstract

This paper describes a novel application of a pattern recognition technique for predicting boundary shear stress distribution in open channels. In this approach, a synthetic database of images representing normalized shear stress distributions is formed from a training data set using recurrence plot analysis. The face recognition algorithm is then employed to synthesize the recurrence plots and transform the original database into short-dimension vectors containing similarity weights proportional to the principal components of the distribution of images. These vectors capture the intrinsic properties of the boundary shear stress distribution of the cases in the training set, and are sensitive to variations of the corresponding hydraulic parameters. The process of transforming one-dimensional data series into vectors of weights is invertible, and therefore, shear stress distributions for unseen cases can be predicted. The developed method is applied to predict boundary shear stress distributions in smooth trapezoidal and circular channels. The results show a cross correlation coefficient above 92%, mean square errors within 0.04% and 4.48%, and average shear stress fluctuations within 2% and 5%, thus, indicating that the proposed method is capable of providing accurate estimations of the boundary shear stress distribution in open channels.

## Introduction

Boundary shear stress is the result of the tangential component of the hydraulic forces that act in the direction parallel to the channel's boundaries and transfer momentum to its bed and walls (Chow, 1959). Excessive shear stress can undermine channel stability by eroding bank sides and cause changes in the river morphology by affecting the transport and deposition of sediments (Julien,

1995). Erosion often results in higher levels of turbidity and lower water quality levels. Furthermore, an increase in sediment movement and deposition can cause a decrease in channel capacity, and consequently, higher flood risk. Computation of flow resistance, side-wall correction, sediment discharge, channel erosion or deposition, cavitation problems, and design of stable channels are among the problems which require accurate estimates of the boundary shear stress distribution (Yang and Lim, 1997; Guo and Julien, 2005; Blanckaert et al., 2010).

The distribution of boundary shear stress over the wetted perimeter of a channel cross-section is non-uniform. This is true even for steady flows in straight prismatic channels with a simple cross-sectional geometry. This non-uniformity is mainly due to the anisotropy of the turbulence which produces transverse gradients of Reynolds stresses and secondary circulations (Gessner, 1973). Tominaga *et al.* (1989) and Knight and Demetriou (1983) showed that the boundary shear stress increases where the secondary currents flow towards the wall, and decreases when they flow away from the wall. Other factors that govern the distribution of shear stress are the geometry of the cross-section, lateral and longitudinal boundary roughness distributions (Blanckaert et al., 2010) and sediment concentration (Khodashenas et al., 2008).

To date, numerous investigations have been conducted and various mechanistic and empirical methods have been developed for understanding and estimating the magnitude and distribution of boundary shear stress. However, due to the complexities involved, boundary shear stress has proven to be one of the most challenging parameters to quantify and measure, even for simple smooth prismatic channels with uniform flow.

For steady uniform open channel flow, an approximation of the average boundary shear stress can be found by applying Newton's second law on a free body, and balancing the downslope component of the fluid weight by the frictional force exerted by the boundary:

$$\bar{\tau} PL = \gamma AL \sin \alpha \quad (1)$$

where  $\bar{\tau}$  is the average boundary shear stress ( $\text{Nm}^{-2}$ ),  $A$  is the channel's cross-section ( $\text{m}^2$ ),  $P$  is the channel's wetted perimeter (m),  $L$  is the reach length (m),  $\gamma$  is water's specific weight ( $\text{kgm}^{-3}$ ) and  $\alpha$  is the slope angle of the channel bed plane. Rearranging Eq. (1) gives:

$$\bar{\tau} = \gamma \sin \alpha \frac{A}{P} = \gamma \sin \alpha R \quad (2)$$

where  $R$  is the hydraulic radius of the channel (m). This simple equation, often referred to as the slope method, is valid for both laminar and turbulent flow regimes, but only provides the average boundary shear stress.

The logarithmic "law of the wall" (Patel, 1965) is another popular and simple method for indirect estimation of the boundary shear stress in rivers and channels. This law, for a two dimensional turbulent flow is given by:

$$\frac{u(z)}{u_*} = \frac{1}{\kappa} \ln \left( \frac{u_* z}{\nu} \right) + C \quad (3)$$

where  $u$  is the time-averaged (mean) streamwise velocity profile ( $\text{ms}^{-1}$ ),  $z$  is the vertical coordinate (m),  $u^*$  is the shear velocity ( $\text{ms}^{-1}$ ) given by  $u_* = (\tau / \rho)^{1/2}$ ,  $\nu$  is the kinematic viscosity ( $\text{m}^2\text{s}^{-1}$ ),  $\kappa$  is the von Karman's constant  $\approx 0.41$  and  $C$  is a dimensionless integration constant related to the thickness of the viscous sub-layer. Although the log law is strictly valid for the turbulent sublayer (approximately the lower 20% of the depth), it is commonly extended over the entire flow depth in rivers and channels (Petrie and Diplas, 2015). If the mean velocity profile,  $u(z)$ , is known, then a simple linear regression (e.g. least squares) can be applied to fit the velocity profile to Eq. (3) and calculate the log law parameters, the shear velocity, and consequently the shear stress. The advantage of this approach is that it does not need detailed information about bed roughness, however it requires measurements of the streamwise velocity profile, and making assumptions for the viscous sublayer thickness, which to some extent limits its applicability and accuracy.

Preston's (1954) method is the most widely practiced technique for measuring boundary shear stress in smooth channels. In this method, a Preston tube is used to infer the velocity of the water flow by recording the difference between static and total pressures. A non-dimensional calibration function is then established based on the "law of the wall", Eq. (3), and used to determine the boundary shear stress from the differential pressures. The simplicity of the experimental setup and its operation are the main reasons behind the popularity of this method. However, for rough boundaries, application of the technique is substantially more complicated, due to the absence of a viscous sublayer. A number of studies (Hwang and Laursen, 1963; Ghosh and Roy, 1970; Hollick, 1976, Hollingshead and Rajratnam, 1980) have attempted to extend the use of this technique to rough surfaces, and have calibrated curves for the Preston tube by using Nikuradse's (1933) model of velocity distribution over rough boundaries. Although promising, these methods can only be applied when the sand equivalent roughness height of the surface is known, which makes them unsuitable for application to a variety of open channels. Other methods based on fitting the log law of the wall such as Clauser's method (1956) and the boundary characteristics method (Hinze 1975, Papanicolaou et al., 2012) have been developed and applied to gradually (Afzalimehr and Anctil, 2000) and rapidly varying flows over spatially varying boundaries (Papanicolaou et al., 2012).

Geometrical methods for estimating shear stress distribution (Leighly, 1932, Einstein, 1942, Lundgren and Johnson, 1964; Khodashenas and Paquier, 1999; Yang and Lim, 1997; 2005, Yu and Tan, 2007; and Abderrezzak et al., 2008) consist of splitting the channel cross-section into sub-regions where the shear force along each segment of the boundary is calculated by balancing the forces against the weight of fluid in the corresponding sub-region. In these approximations, mapping and discretising the wetted perimeter is often a complicated and sensitive task, however, they have the advantage of requiring relatively low computational effort.

99 Where abundant experimental data existed, researchers (e.g. Knight, 1981; Knight et al., 1984,  
100 1994; Flinham and Carling, 1988; Pizzuto, 1991; Olivero et al., 1999) have used regression and  
101 correlation analysis to derive empirical and semi-empirical equations for boundary shear stress.  
102 These equations are capable of only calculating mean, maximum and percentages of shear stress  
103 carried on the channel's walls and beds with relatively good accuracy, but are unable to provide the  
104 distribution of shear stress along the entire wetted perimeter. Some other researchers (e.g. Zheng  
105 and Jin, 1998, Jin et al., 2004; Guo and Julien, 2005 and Bilgil, 2005) have solved the governing  
106 energy transport, continuity, and momentum equations to formulate analytical and semi-analytical  
107 solutions for calculating the boundary shear stress. These methods often rely on a number of  
108 subjective and controversial assumptions and require a large amount of computing resources which  
109 make them impractical. With the advent of more powerful computers, Computational Fluid Dynamic  
110 (CFD) techniques have been also used (e.g. Christensen and Fredsoe, 1998; De Cacqueray *et al.*,  
111 2009) to solve the referred set of equations and calculate the boundary shear stress distribution.  
112 Nonetheless, these methods are computationally expensive and the model outputs are extremely  
113 sensitive to mesh size, the turbulence closure model, and other internal parameters which are  
114 defined by the user.

115 Recently, information theory and machine learning techniques have been used to tackle this  
116 problem. For instance, the principle of maximum entropy has been used (e.g. Sterling and Knight,  
117 2002; Li and Zhang, 2008; Bonakdari et al., 2015) to establish relationships for the boundary shear  
118 stress. A comparison with experimental data has shown that these approximations provide relatively  
119 flat shear stress distributions which make them unreliable. The divergence between the numerical  
120 and experimental results increases at the regions around the corners of the sections where  
121 secondary flow structures are more pronounced. Cobaner et al. (2010) used a neural network with  
122 4 hidden layers to predict the percentage of the shear force acting on the walls of smooth rectangular  
123 channels and ducts. The study concluded that the ANN predictions were less biased and slightly  
124 more accurate than the classic empirical models suggested by Knight et al. (1984) and Knight and  
125 Patel (1985).

126 Measuring the actual local shear stress along the channel's boundaries is difficult and costly owing  
127 to the complexity of the turbulent velocity field, presence of flow structures, and the small magnitude  
128 of the stress. Shear stress also represents a difficult parameter to calculate due to the variability of  
129 channel slope, geometry and flow structures, which are the main influencing factors in the complex  
130 flow process. To date, all the developed methods are inherently based on some sort of simplifying  
131 assumption, and therefore, the problem of accurately estimating these stresses has only been  
132 partially resolved (Zheng and Jin, 1998).

133 The recent relative abundance in available experimental data has offered an opportunity to test and  
134 validate novel techniques for describing the boundary shear stress distribution. In this paper, an  
135 advanced pattern recognition technique is employed to predict the distribution of boundary shear

136 stress in open channels. This technique, which results from merging two existing algorithms  
137 (Recurrence Plots and Eigenfaces for Recognition), is combined with a standard regression model  
138 for the prediction of data series representing shear stress distribution of flows with known attributes  
139 (i.e. Froude numbers, flow depths and channel slopes).

140 In the following Sections the Recurrence Plot analysis and its adaptation to the Eigenfaces for  
141 Recognition is explained. This is followed by a description of the experimental data used in the study  
142 and details of the proposed methodology. Next, the prediction of boundary shear stress distributions  
143 in trapezoidal and circular channels are presented and critically discussed. The paper concludes  
144 with a discussion on the advantages of the method and suggestions for improvement.

## 145 **Background**

146 The proposed approach for predicting boundary shear stress distribution combines Recurrence Plot  
147 (RP) analysis (Eckmann et al., 1987) and Eigenfaces for Recognition (Turk and Pentland, 1991). RP  
148 is used to transform one-dimensional data series into two-dimensional arrays which can be  
149 graphically represented. Eigenfaces for Recognition is then used as a means of identifying patterns  
150 in the arrays and to transform these into short-dimension vectors which can then be used to predict  
151 boundary shear stress distributions. It is to note that despite using a method that was originally  
152 developed for the recognition of human faces using 2D still images; no “recognition” is involved in  
153 the proposed methodology. Instead, the technique is used to filter the original data and reduce its  
154 dimensionality whilst preserving intrinsic qualities. These reduced databases are then used to  
155 produce shear stress distribution for unseen cases.

## 156 **Recurrence Plots**

157 Recurrence Plots are visualization tools that can be used to picture the recurrence behaviors, hidden  
158 patterns and nonlinearities in data sets (Marwan et al., 2007). In this technique, starting from the first  
159 point of a data series,  $d$ -dimensional vectors are formed by taking a sample of  $d$  consecutive points  
160 in the data series:

$$\begin{aligned} \vec{q}_j &= \{q_j, q_{j+1}, \dots, q_{j+d-1}\} \\ &\vdots \\ \vec{q}_k &= \{q_k, q_{k+1}, \dots, q_{k+d-1}\} \end{aligned} \quad (4)$$

161 where subscripts  $j$  and  $k$  represent the  $j^{\text{th}}$  and  $k^{\text{th}}$  data points in the data series. The  $d$ -dimensional  
162 vectors are then correlated by calculating the Euclidean distance between them. This parameter can  
163 then be used to form the RP matrix:

$$RP = \begin{bmatrix} e_{11} & e_{12} & \cdots & e_{1N} \\ e_{21} & e_{jk} & & \vdots \\ \vdots & & \ddots & \vdots \\ e_{N1} & \cdots & \cdots & e_{NN} \end{bmatrix} \quad (5)$$

164 where  $e_{jk}$  is the distance between vectors  $\vec{q}_j$  and  $\vec{q}_k$  and  $N$  is the total number of vectors, which  
 165 define the number of data points in each column and row of the matrix. Note that the values of  $e_{jk}$  in  
 166 the RP matrix vary with  $d$  whilst any value of  $d$  would result in a matrix that could be used in the  
 167 recognition method as described further below. However by letting  $d = 1$  each row in the RP matrix  
 168 effectively becomes a normalized version of the original one-dimensional data series which has the  
 169 benefit of maintaining its basic structure throughout the pattern recognition process.

170 By projecting the RP matrix on a Cartesian space, a map of the data can be generated. In this case  
 171 each pixel on the map has the coordinates  $\{j, k\}$  with  $j, k = 1, 2, \dots, N$ , as well as a numerical value  
 172 that is proportional to its associated distance,  $e_{jk}$ . In an 8-bit grayscale image representation, the  
 173 values of  $e_{jk}$  can take values within the range 0 to 255, where the brightness intensity of each pixel  
 174 indicates a larger  $e_{jk}$ . Through the calculation of the  $RP$  matrix, the correlation between all data points  
 175 within the data series is established whilst preserving the basic structure of the database. Such  
 176 transformation and visualization helps to make explicit features of data which otherwise would be  
 177 difficult to observe in the original series.

178 The graphical representations of  $RPs$  helps to visualize characteristic patterns of the data, although  
 179 for numerical analysis, its elements need to be sorted in a  $N^2$  dimension vector where all rows of the  
 180  $RP$  matrix are assembled in sequence:

$$\Gamma^T = \{e_{11}, e_{12}, \dots, e_{NN}\} \quad (6)$$

181 The arrangement of columns of the RP matrix into the  $\Gamma$  vector is schematically shown in Figure 1.  
 182 The unique configuration of RPs makes them particularly suitable for machine learning. That is  
 183 because pattern recognition methods are capable of identifying data sets with unique features such  
 184 as those made explicit through the RP method. In the following sections the post-processing of  
 185  $\Gamma$  vectors and their relationship with the hydraulic parameters that control shear stress distributions  
 186 is discussed in detail.

Recurrence Plot

Figure 1. Relationship between the RP matrix and the  $\Gamma$  vector.

### Eigenfaces for Recognition

The Eigenfaces for Recognition is based on the premise that any 2D image of resolution  $N \times N$  can be represented by an  $N^2$  size vector  $\Gamma$ , where each element is a real number that represents an individual pixel in the image. If the training set consists of  $M$  images, then the average face of the training set,  $\mathcal{G}$ , is defined by:

$$\mathcal{G} = \frac{1}{M} \sum_{i=1}^{i=M} \Gamma_i \quad (7)$$

and hence, the difference between each image,  $\Gamma_i$ , and the average face,  $\mathcal{G}$ , is given by:

$$\phi_i = \Gamma_i - \mathcal{G}; \quad i = 1, 2, \dots, M \quad (8)$$

Performing principal component analysis (PCA) on the collection of all  $\phi_i$ , would result in a set of  $M$  orthonormal vectors which best describe the distribution of data. PCA is a statistical procedure that is able to identify orthogonal modes or degrees of freedom within a numerical array, and transform a number of possibly correlated variables into a smaller number of uncorrelated variables, which are called the principal components. The eigenvectors and eigenvalues of these principal components can be determined from the covariance matrix:

$$C = AA^T \quad (9)$$

where

$$A = [\phi_1, \phi_2, \dots, \phi_M] \quad (10)$$

Matrix  $C$  is of size  $N^2$ , and finding its eigenvectors and eigenvalues is computationally expensive. If the number of training images,  $M$ , is less than the dimension of the space,  $N^2$ , then there will only be  $M-1$  meaningful eigenvectors (Turk and Petland, 1991), and hence, to reduce the calculations, an  $M$  by  $M$  matrix  $L$  can be constructed to find the meaningful eigenvectors:

$$L = A^T A \quad (11)$$

206 where

$$L_{ij} = \phi_i^T \phi_j \quad (12)$$

207 The principal components of the distribution of images are called the eigenfaces,  $u_l$ , which can be  
208 calculated from a linear combination of the images and eigenvectors:

$$u_l = \sum_{i=1}^M v_{li} \phi_i \quad l = 1, \dots, M \quad (13)$$

209 where  $v_{li}$  is the  $l^{\text{th}}$  eigenvector of the covariance matrix. The collection of eigenface vectors defines  
210 a subspace of training images which is called the “*face space*”. Any input image expressed in vector  
211 form  $\Gamma$ , can be projected into the *face space* through the following operation:

$$\omega_i = u_i^T (\Gamma - \mathcal{G}), \quad i = 1, \dots, M' \quad (14)$$

212 where  $\omega_i$  is a weight factor that describes the contribution of the  $i^{\text{th}}$  eigenface in representing the  
213 image, and  $M'$  is the number of significant eigenvectors, associated with the  $M$  largest eigenvalues  
214 i.e.  $M' \leq M$ . Furthermore, the set of weights ordered in a short-dimension vector  $\Omega^T = \{\omega_1, \omega_2, \dots, \omega_{M'}\}$   
215 can be used to project any new image,  $\Gamma'$ , into the *face space* by:

$$\Omega = U^T (\Gamma' - \mathcal{G}), \quad i = 1, \dots, M' \quad (15)$$

216 where  $U = \{u_i\}$  is the collection of eigenfaces. Eq. (15) suggests that the process of encoding data into  
217  $\Omega$  vectors can be inverted for prediction purposes. If a reliable estimation of weights factors is  
218 available to conform a new vector  $\Omega'$ , then a prediction of its associated image can be made through:

$$\Gamma' = U \Omega' + \mathcal{G} \quad (16)$$

219 As will be further explained in the following sections, a reliable estimation of the weight factors, i.e.  
220 vector  $\Omega'$ , would be based on the known vectors obtained through Eq. (15) together with the  
221 parameters that characterize the original data sets. These vectors and parameters can be typically  
222 related with the aid of a simple regression model or more complicated method such as an artificial  
223 neural network, and the output  $\Omega'$  can be considered to be reliable if the modeling error is less than  
224 5%. Note that the validity of Eq. (16) is provided in Appendix A.

## 225 **Experimental datasets**

226 In this study, laboratory measurements of flow velocity and boundary shear stress in trapezoidal and  
227 circular open channels were taken directly from the University of Birmingham’s Flow Database  
228 ([www.flowdata.bham.ac.uk](http://www.flowdata.bham.ac.uk)).

## 229 Trapezoidal datasets

230 Two sets of experimental data relating to uniform flow in trapezoidal channels were used in this  
231 study: Yuen (1989) and Yuen and Knight (1990). The data included local boundary shear stress  
232 measurements in trapezoidal channels (Figure 2) using a Preston tube, made in fully developed flow  
233 under uniform flow conditions in a 22 m long tilting flume. Two different base widths ( $2b$ ) of 0.15m  
234 and 0.45m were considered, and the bed slope was varied from  $1 \times 10^{-3}$  to  $2.337 \times 10^{-2}$  in order to  
235 observe shear stress distribution for Froude ( $Fr$ ) and Reynolds ( $Re$ ) numbers within ranges of  $0.58$   
236  $\leq Fr \leq 3.59$  and  $0.46 \times 10^5 \leq Re \leq 6.18 \times 10^5$ , respectively, which derives from flow velocities ( $V$ )  
237 between  $0.39 \text{ ms}^{-1}$  and  $2.69 \text{ ms}^{-1}$ . Measurements of velocity and shear stress were taken on average  
238 every 20 mm along the wetted perimeter (i.e. between 16 and 32 measurement points for each  
239 case), and measurement accuracy was estimated to be within  $\pm 5\%$  (Yuen, 1989).

240 Figure 2. Trapezoidal channel cross section.

241 To obtain homogenous subsets suitable for pattern recognition, and to test the sensitivity of the  
242 approach to the size of the training set, k-nearest neighbors (k-nn) clustering analysis (Fix and  
243 Hodges, 1951) was first performed. The fundamental idea of the k-nn algorithm is to simply separate  
244 the data based on the assumed similarities between various clusters. Here, the Euclidean distance  
245 metric was used to measure the similarity between clusters, and shear stress data was non-  
246 dimensionalized by the average shear stress to eliminate the scale effects. K-nn was run with  
247 different  $k$  values, and consequently, three clusters (subsets) were identified by investigating the  
248 resultant dendrograms, i.e. graphical tree-structures that show the hierarchical relationships among  
249 clusters, ensuring highest similarity within each cluster (homogeneity) and lowest similarity between  
250 clusters were achieved.

251 Table (1) lists the geometric and hydraulic parameters of all the experiments. In each subset, one  
252 experiment (highlighted in Table 1) was randomly selected and excluded to be used for validation  
253 whilst the remaining were considered for training. Since the method requires all data series in the  
254 set to have the same number of measurements taken at relatively even distances, for each  
255 experiment, the horizontal coordinates of all data points were normalized using a perimetric distance  
256 defined as  $Pd = s/p$ , where  $s$  is the distance along the wetted perimeter starting at the left bank at  
257 the free surface, moving around the wetted perimeter, and  $p$  is the total length of the wetted  
258 perimeter. The shear stress measurements in each experiment were also non-dimensionalized by  
259 the average shear stress. Where required, linear interpolation was used to obtain shear stress values  
260 from adjacent neighboring points. It is to note that at regions where shear stress varied at higher

261 rates, experimental measurements were taken at smaller increments, thus resulting in the  
 262 standardization of the degree of accuracy across the wetted perimeter.

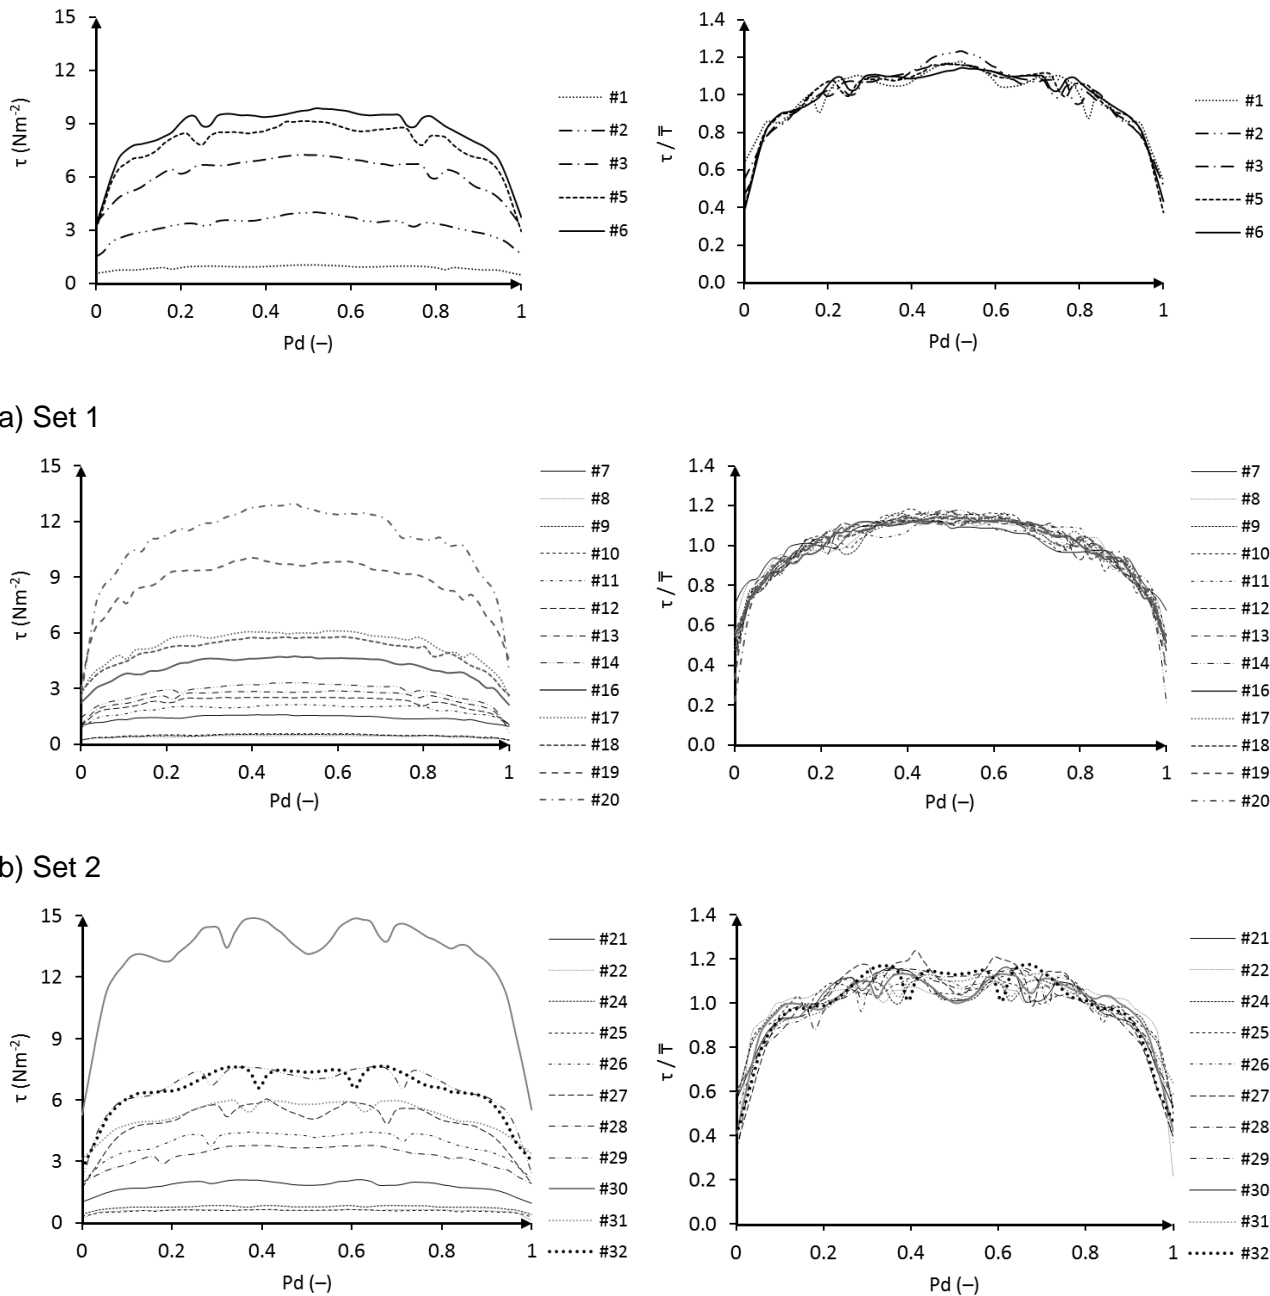

263 Figure (3) shows the distribution of the measured and non-dimensionalized shear stress for each of  
 264 the three sets. It can be seen that the data series corresponding to each set share patterns such as  
 265 the location of peak values and inflection points, which are attributed to the secondary flow  
 266 structures, and the range of shear stress fluctuations across the wetted perimeter.

## 271 Circular Channels

272 A separate set of experimental data containing local boundary shear stress measurements in a  
 273 circular channel, with and without a flat bed, running partially full was also used in this study (Figure  
 274 4). This data has been described and analyzed in detail by Sterling (1998), Knight and Sterling (2000)  
 275 and Sterling and Knight (2000).

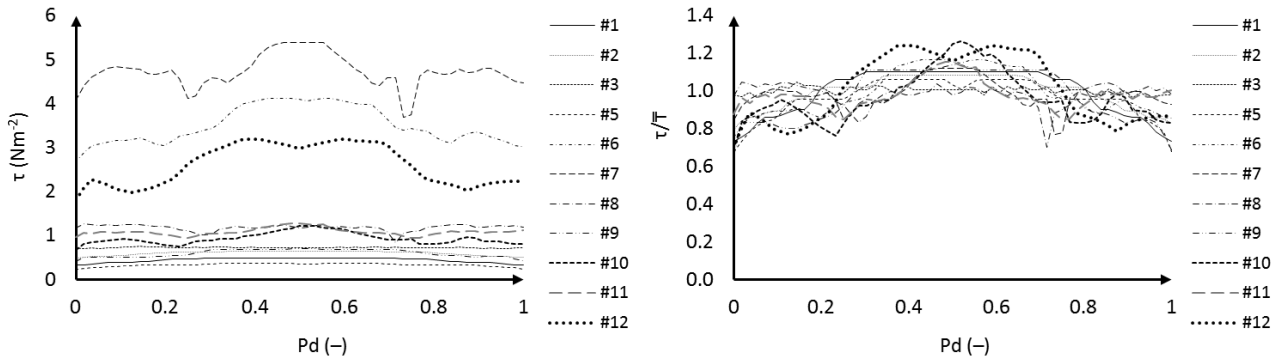

Figure 4. Circular channel cross section.

Similar to the trapezoidal data, k-nn clustering analysis was performed and only one major cluster was identified. It is to note that for this particular data set, even if the clustering was performed in a different way (e.g. with a different distance measure or clustering technique) and more than one cluster was obtained, the quality of the prediction would increase, given enough data is available for training the model. The only major difference would be the increased computation required for the extra clusters. Hence, in this context, one can see clustering as the process to find the optimum data sets on which modelling can be applied to without losing accuracy. Table (2) lists the geometric and hydraulic parameters of all the circular channel test cases. Two validation cases, labelled CVc-1 and CVc-2, were randomly chosen to validate the method and were excluded from the training set. The local shear stresses were originally measured at 10mm intervals around the wetted perimeter using a Preston tube. Hence, the difference in water depth between experiments resulted in different number of measurements in each data series, ranging from 30 to 60 point measurements. Similar to what was done for the trapezoidal case studies, a perimetric distance,  $Pd$ , was used to uniformize the number of measurements along the wetted perimeter. Where data points did not exist in the original series, linear interpolation was used to infer local boundary shear stress from adjacent neighboring points. Figure (5) depicts the boundary shear stress distribution of the cases in the training set.

## Methodology

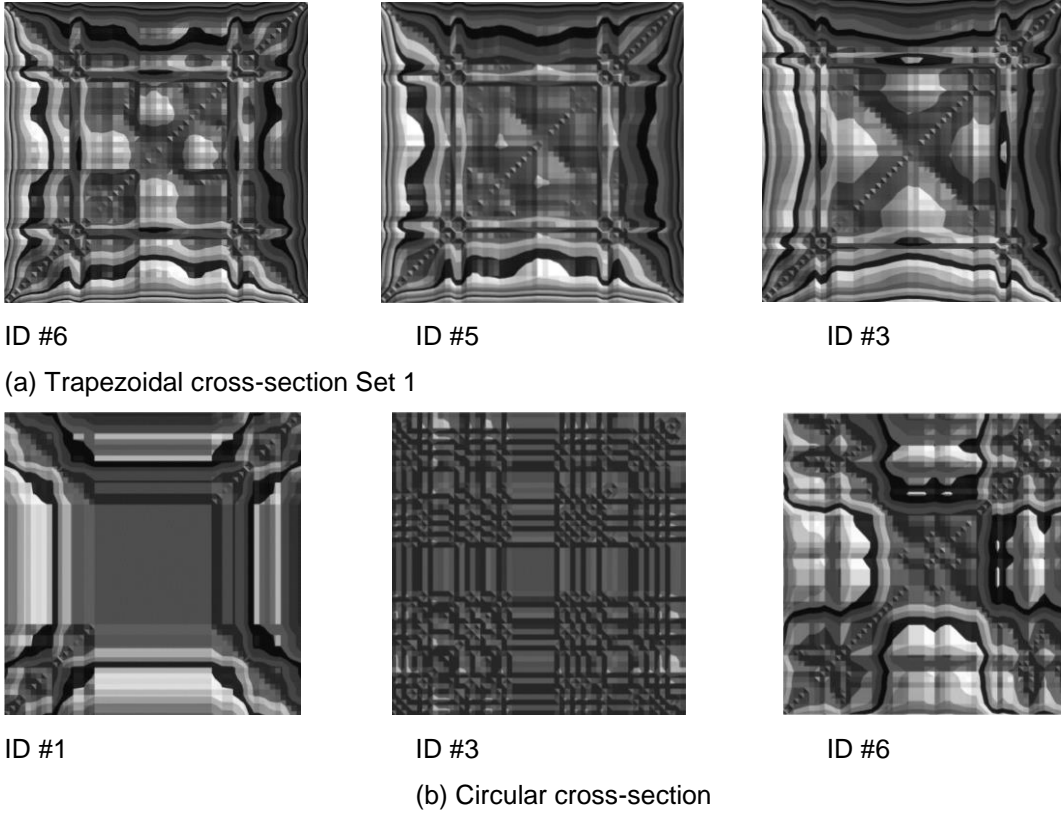

The initial step in using Recurrence Plots and Eigenface Recognition for predicting boundary shear stress distribution is forming a training set from available experimental data. As mentioned in the previous section, the raw experimental data sets typically consist of a number of local boundary shear stress measurements, taken along the wetted perimeter of a channel, and presented as a data series. If measurements are not taken at the same relative locations across the different channels, then, to make the raw data suitable for use in the data mining algorithm, interpolation is carried out to find shear stresses at the same relative distances along the wetted perimeter, for all data series.

As the Eigenfaces for Recognition algorithm accepts two-dimensional arrays of numbers, the original (one-dimensional) data series in the training set has to be pre-processed. This can be done through the Recurrence Plot algorithm. To this end, the dimension of the  $\vec{q}$  vectors identified in Eq. (4) is set to be equal to 1, so that each vector would contain numerical differences of shear stress between consecutive points in the data series, effectively resulting in each row of the RP matrix to become a normalized version of the original data series. In line with the image recognition algorithm, once the RP matrix is formed, Eq. (6) is used to construct a unique  $\Gamma_i$  vector representing the  $i$ -th experimental data set.

Figure (6) shows the recurrence plots for the shear stress distribution of selected trapezoidal and circular data sets. It can be seen that the patterns of RPs associated to trapezoidal sections are fairly consistent. There is a square region at the center of most images whose silhouette stretches along the diagonals more than it does towards the sides. This does not appear to be the case for circular

319 cases (Figure 6b) where the RPs follow at least three types of patterns. The consistency of the  
 320 datasets is also present in the original series shown in Figures 3 and 4 although the use of the RP  
 321 technique has made those intrinsic properties more explicit. That is the main reason for pre-  
 322 processing the data prior to applying the full recognition method. As will be shown in the Results  
 323 Section, the apparent constraint found in data from circular channels did not have a significant impact  
 324 on the prediction of shear stress distributions.

325

326 Figure 6. Recurrence Plots of selected a) Trapezoidal and b) Circular channels.

327 Once the Recurrence Plot vector representation for all members of the training set are obtained, Eq.  
 328 (7) is used to calculate the average face,  $\mathcal{Q}$ , and consequently, the difference between each image  
 329 in the training set and the average face,  $\phi$ , are found by using Eq. (8). Then, performing Principal  
 330 Component Analysis, the eigenvectors that characterize the face space are computed, and  
 331 consequently, the set of weights,  $\Omega$ , are determined by using Eq. (14). Figure (6) outlines the steps  
 332 involved for encoding the training data sets and obtaining the vectors of weights,  $\Omega$ .

Figure 7. Process of encoding data series of shear stress.

As mentioned in the background Section, to use this approach for predicting the boundary shear stress distribution of an unseen case, i.e. experimental data not included in the training set, also hereafter referred to as a validation case, a set of weights must be obtained to be used in Eq. (16). For the sake of generality, the weights associated to any experimental case are related to non-dimensional parameters which represent the major characteristics of channel's geometry and flow. In this research we have used the following non-dimensional attributes:

- Trapezoidal channels:  $2b/h$ ,  $2bh/A$ ,  $Fr$ ,  $Re$
- Circular channels:  $(h+t)/D$ ,  $Q/(VD^2)$ ,  $Fr$ ,  $Re$

Where  $h$  is the water depth,  $V$  is the mean velocity,  $Q$  represents discharge, and  $Fr$  and  $Re$  are the Froude and Reynolds numbers, respectively. The bottom width for trapezoidal channels is represented by  $2b$  whilst  $t/D$  is the base height to diameter ratio for circular channels. In order to relate weights and non-dimensional attributes, a simple regression model can be established:

$$\omega_i = \beta_1 x_{i1} + \beta_2 x_{i2} + \dots + \beta_n x_{in} \quad (17)$$

where  $\omega_i$  represents a regression estimation of the  $i$ -th weighting factor,  $x_{ij}$  is the  $j$ -th non-dimensional hydraulic/geometric parameter of the  $i$ -th training experiment and  $\beta_j$  are regression parameters. The solution to Eq. (17) is given by:

$$\beta = (X^T X)^{-1} X^T \Omega \quad (18)$$

where  $\hat{\beta}$  is the best estimator vector of the target  $\beta$  factors  $X$  represents the matrix of hydraulic/geometric non-dimensional parameters, and  $\Omega$  is the vector of target weighting factors. Once the set of  $\beta$  factors is determined, the prediction model can be established. After investigating a number of non-dimensional attributes, the ones listed above were found to strongly influence the established relationship with the target weighting factors.

Figure (6) shows the steps involved in the process of encoding the original data series. This process can be reversed to obtain a new set of weighting values,  $\omega_i$ , e.g. for test cases not included in the training set. Eq. (17) enables to find those weighting factors which can then be stored in the short-dimension vector ( $\Omega'$ ). Following, The vector  $\Gamma'$  can be predicted by applying Eq.(16).

To help the reader better understand the entire modeling process, a simple step-by-step guide to using the proposed approach is presented in Appendix B. Furthermore, a copy of the code written in C++ is available at: <http://shear-stress-using-face-recog.sourceforge.net>

## Results

## 362 **Trapezoidal Channels**

363 The proposed methodology was first applied to the three trapezoidal data sets presented in Table  
364 (1). In summary, for each training set, the process shown in Figure (6) was first followed to obtain  
365 the weight factors for the training set,  $\Omega$ . Then, Eq. (17) was used to establish a linear regression  
366 between the weights associated with each eigenface and the non-dimensional attributes of the  
367 geometric and hydraulic parameters of the experiments. The corresponding  $\beta$  regression parameters  
368 were then obtained using Eq. (18) and the vector of estimated weights for the unseen test case,  $\Omega'$   
369 was constructed. All weighting and  $\beta$  factors are provided in Appendix C. Subsequently, Eq. (16)  
370 was used to obtain the  $\Gamma'$  vector, and its elements were transformed to find non-dimensionalised  
371 shear stress values across the channel. It should be noted that the first component of the  $\Gamma'$  vector,  
372 i.e.  $e_{11}$ , which corresponds to the boundary shear stress value at  $Pd = 0$  is always zero. The boundary  
373 shear stress at this point was obtained through a separate linear regression between the predicted  
374 values of local shear stresses:

$$\tau_{0i} = \beta_1 x_{i1} + \beta_2 x_{i2} + \dots + \beta_n x_{in} \quad (19)$$

375 where  $\tau_{0i}$  represents a regression estimation of the  $i$ -th shear stress at  $Pd = 0$ ,  $x_{ij}$  is the  $j$ -th non-  
376 dimensional hydraulic/geometric parameter of the  $i$ -th training experiment and  $\beta_j$  are regression  
377 parameters.

378 Finally, the predicted series were rescaled by multiplying their ordinates by the estimated average  
379 shear stress ( $\bar{\tau}$ ) obtained by the Slope method (Eq. 1). For practical purposes, this parameter could  
380 be estimated using any other prediction model, such as the ones suggested by Knight (1981), Knight  
381 et al., (1984&1994) and Flinham and Carling, (1988).

382 Figure (7) shows the predicted vs. observed boundary shear stress distributions for the validation  
383 cases in each of the two sets along with the predictions of the well-established Shiono and Knight  
384 model (SKM) (Shiono & Knight, 1988; 1990). As it can be seen, although there is some difference  
385 between the observed and predicted values particularly at the edges of the wetted perimeter, the  
386 shape and amplitude of the predicted curves accurately follow the observed distributions. Moreover,  
387 the proposed method outperforms SKM in all three cases, particularly at the edges. It is also inferred  
388 that the relatively small number of experiments in training Set 1 did not have a significant impact on  
389 prediction accuracy. The mean square error (MSE) between observed and predicted ordinates  
390 averaged over all data points along the wetted perimeter was found to be of 4.4%, 0.88%, and 0.04%  
391 for TVC-1, 2, and 3, respectively. Table (3) shows a more detailed comparison between observed  
392 and simulated data series for the validation cases. In this table  $|\Delta \bar{\tau}|$  is the average absolute  
393 difference between the ordinates of the observed and predicted data series,  $|\Delta \tau_{\max}|$  is the largest  
394 estimated difference and  $MSE_{SKM}$  is the mean square error for the SKM model. The table also

395 provides the ratio of those divergence parameters with respect to the average stress, in addition to  
 396 the relative location of  $\Delta\tau_{peak}$  along the wetted perimeter covering an interval [0-1], with 0 and 1  
 397 corresponding to the utmost left and right edges of the wetted perimeter, respectively. Furthermore,  
 398 the cross correlation,  $\rho_\tau$ , between the observed and predicted time series is presented for each  
 399 case:

$$\rho_\tau = \frac{1}{N} \left[ \sum_{i=1}^N (\tau_{obs} - \bar{\tau}_{obs})(\tau_{model} - \bar{\tau}_{model}) / \sigma_{obs} \sigma_{model} \right] \quad (21)$$

400 where  $\bar{\tau}$  is the average shear stress and  $\sigma$  is the corresponding standard deviation.

### Circular Channels

The methodology was also applied to the circular channel data set introduced in the Experimental Datasets Section. Figure (8) shows the modelled vs. measured shear stress distribution for the validation test cases. The MSE between observed and predicted values were found to be 0.12% in the first case, CVc-1, and 4.9 % in the second validation case, CVc-2, which are of similar order than those found for the trapezoidal cases. The largest divergence was obtained at the channel edges ( $Pd = 0, 1$ ) which seems to be a reflection of the scatter of the input data shown in Figure (4). It is also noted from Figure (8) that the predicted curves tend to be smoother than the observed ones. This can be due to a *group* effect which causes the predicted shear distributions to tend to the average face value established in the face space. This effect is to some extent implicit in Eq. (8). Nonetheless, the cross correlation parameter, which is well above 0.9 in both cases, together with the magnitude of the differences indicate that the shear stress contours have been captured with excellent accuracy. Table (4) provides an extended comparison between observed and predicted data for circular validation test cases.

## Summary and Conclusions

Recurrence Plot analysis and Eigenface for Recognition were used to predict the distribution of boundary shear stress in trapezoidal and circular channels. In this approach, first, the RPs of all training set members are constructed and the differences between them and the average RPs are computed. Principal component analysis is then performed and weight factors proportional to the eigenvectors are obtained. To obtain predictions of boundary shear stress, a simple regression

equation is established to relate the weight factors to non-dimensional attributes of the training set's hydraulic and geometric characteristics. For each validation case, corresponding weights are obtained by the regression equations, and the reverse of the process is performed to obtain the distribution of the boundary shear stress.

The method was applied to two trapezoidal data sets and one circular data set. The results showed that:

- The technique is capable of capturing the intrinsic patterns of the RPs which makes it suitable for the prediction of shear stress distributions.
- The method is valid for both sub and supercritical flow conditions.
- The average error obtained across all predicted series is of 2.09% and the cross correlation is within 92% of accuracy for all trapezoidal and circular verification cases.

The accuracy of the predictions was found to be somewhat higher for trapezoidal channels compared to circular channels. This can be a reflection of the consistency of the input information which in the case of circular channels is less, i.e. the distributions are less uniform. The variation of the shape of the wetted section with the increase of the water level appears to be the reason of such variability.

The present investigation was based on a database formed by a limited number of experimental test cases, particularly for the case of circular sections. Nevertheless, the prediction results were satisfactory. The robustness of the methodology should be further tested with a larger training database containing further combinations of hydraulic parameters and section dimensions, and additional validation cases. This would help to ensure the generality of the weighting factors, and therefore, the overall accuracy of the prediction models. Based on the analysis presented here it is clear that the method works for relatively low number of input data series which in this research ranged between 5 and 13 data series in the clusters. Furthermore, the linear regression models were demonstrated to be adequate estimators for the relatively smooth bed shear stresses studied, as they were able to capture the rates of shear stress variation with accuracy. It is to note that such simple estimators might not be accurate when modelling more complex configurations and patterns, and a more robust estimator (e.g. artificial neural network) may be more suitable depending on the degree of non-linearity observed in the input data.

574

575 **Appendix A: Derivation of Eq. (16)**

576 From (15) we have:

$$\Omega = U^T (\Gamma - \mathcal{G}) \quad (\text{A1})$$

577 Expanding gives:

$$\Omega = U^T \Gamma - U^T \mathcal{G} \quad (\text{A2})$$

578 Therefore,

$$U^T \Gamma - \Omega = U^T \mathcal{G} \quad (\text{A3})$$

579 Since the matrix  $U$  is orthogonal  $U^T = U^{-1}$ , and therefore:

$$UU^{-1} \Gamma = UU^{-1} \mathcal{G} + U \Omega \quad (\text{A4})$$

580 Finally leading to,

$$\Gamma = \mathcal{G} + U \Omega \quad (\text{A5})$$

581

Step No.	Action	Detail	Comment
1	Integrate database	It will contain M data series	
2	Take sample vectors of dimension $d$	$\vec{q}_j = \{q_j, q_{j+1}, \dots, q_{j+d-1}\}$ $\vdots$ $\vec{q}_k = \{q_k, q_{k+1}, \dots, q_{k+d-1}\}$	
3	Calculate Euclidean distance amongst $q$ -vectors	$e_{jk}$ : Euclidean Distance between $q_j$ and $q_k$	
4	Assemble RP Matrix  There will be one RP Matrix per data series.	$RP = \begin{bmatrix} e_{11} & e_{12} & \dots & e_{1N} \\ e_{21} & e_{jk} & & \vdots \\ \vdots & & \ddots & \vdots \\ e_{N1} & \dots & \dots & e_{NN} \end{bmatrix}$	Project RP Matrix on Cartesian space to plot RP if required
5	Form M vectors of dimension $N^2$	$\Gamma^T = \{e_{11}, e_{12}, \dots, e_{NN}\}$	
6	Estimate the average $\Gamma$ vector ( $\vartheta$ ) and its fluctuating components ( $\phi_i$ )	$\vartheta = \frac{1}{M} \sum_{i=1}^{i=M} \Gamma_i; \phi_i = \Gamma_i - \vartheta; i = 1, 2, \dots, M$	
7	Assemble A Matrix and related covariance matrix	$A = [\phi_1, \phi_2, \dots, \phi_M]; C = AA^T$	
8	Perform eigenvalue and eigenvector analysis on matrix C	$u_l$ : $l$ -th eigenvector of matrix C if the reduced matrix $L$ were used then, $u_l = \sum_{i=1}^M v_{li} \phi_i \quad l = 1, \dots, M$	Alternatively, calculate eigenvectors from a reduced matrix L $L = A^T A$
9	Determine M weighting factors ( $\omega$ ) to assemble the short-dimension vectors $\Omega$	$\omega_i = u_i^T (\Gamma - \vartheta), \quad i = 1, \dots, M'$ $\Omega^T = \{\omega_1, \omega_2, \dots, \omega_{M'}\}$ where $M'$ is the number of meaningful eigenvectors	There will be one $\Omega$ vector per original data series
<b>Prediction Process</b>			
10	Put together estimators for predicting new sets of $\Omega$ vectors for cases not included in the original database as well as for predicting the initial value of the data series ( $\tau_0$ )	Given the estimation of $\Omega'$ the corresponding $\Gamma'$ vector can be calculated, $\Gamma' = U\Omega' + \vartheta$ $\tau_0$ : estimated value of shear stress at Pd=0	Estimators could be based on linear regression models or machine learning techniques
11	Infer the $RP'$ Matrix	See Step 4	
12	Infer predicted data series	Any row in the $RP'$ Matrix represents a normalized version of the predicted data series	Select Row 1
13	Denormalize the predicted series	Rescale the selected row in the $RP'$ Matrix by using the estimated value of $\tau_0$	End of prediction process

584 **Appendix C: Weighting and  $\beta$  factors**

585

609

610 The weighting factors represent the components of the vector  $\Omega^T$  in step 9 of the algorithm - as described in  
611 Appendix B, and are the base to setup the estimator for predicting new sets of  $\Omega$  vectors not included in the  
612 original data set as outlined in step 10 of the same procedure.
